Abstract. Briefly summarize the contents of the paper in 150–250 words.

Keywords: numerical, linear, algebra, types, permissions, OCaml

1 Introduction

NumLin is a functional programming language designed to express the APIs of low-level linear algebra libraries (such as BLAS/LAPACK) safely and explicitly. It does so by combining linear types, fractional permissions, runtime errors and recursion into a small, easily understandable, yet expressive set of core constructs.

NumLin allows a novice to understand and work with complicated linear algebra library APIs, as well as point out subtle aliasing bugs and reduce memory usage in existing programs. In fact, we were able to use NumLin to find linearity and aliasing bugs in a linear algebra program that was generated by another program specifically designed to translate matrix expressions into an efficient sequence of calls to linear algebra routines. We were also able to reduce the number of temporaries used by the same program, using NumLin's type system to guide us.

NumLin's implementation supports several syntactic conveniences as well as a *usable* integration with real OCaml libraries.

1.1 Contributions

In this paper

- we describe Numlin, a linearly typed language for linear algebra programs
- we illustrate that NumLin's design and features are well-suited to its intended domain with progressively sophisticated examples
- we prove Numlin's soundness, using a step-indexed logical relation
- we describe a very simple, unification based type-inference algorithm for polymorphic fractional permissions (similar to ones used for parametric polymorphism), demonstrating an alternative approach to dataflow analysis [1]
- we describe an implementation that is both compatible with and usable from existing code

- we show an example of how using NumLin helped highlight linearity and aliasing bugs, and reduce the memory usage of a generated linear algebra program
- we show that using NumLin, we can achieve parity with C for linear algebra routines, whilst having much better static guarantees about the linearity and aliasing behaviour of our programs.

2 NumLin Overview and Examples

2.1 Overview

Linearity is at the heart of NumLin. Linearity allows us to express a purefunctional API for numerical library routines that mutate arrays and matrices. Linearity also restricts aliasing of (values which represent) pointers.

Intuitionism: ! and Many However, linearity by itself is not sufficient to produce an expressive enough programming language. For values such as booleans, integers, floating-point numbers as well as pure functions, we need to be able to use them *intuitionistically*, that is, more than once or not at all. For this reason, we have the ! constructor at the type level and its corresponding Many constructor and let Many <id> = . . in . . eliminator at the term level. Because we want to restrict how a programmer can alias pointers and prevent a programmer from ignoring them (a memory leak), Numlin enforces simple syntactic restrictions on which values can be wrapped up in a Many constructor (details in Section 3).

Fractional Permissions There are also valid cases in which we would want to alias pointers to a matrix. The most common is exemplified by the BLAS routine gemm, which (rather tersely) stands for $GEneric\ Matrix\ Multiplication$. A simplified definition of gemm(α , A, B, β , C) is $C:=\alpha AB+\beta C$. In this case, A and B may alias each other but neither may alias C, because it is being written to. Related to mutating arrays and matrices is freeing them. Here, we would also wish to restrict aliasing so that we do not free one alias and then attempt to use another. Although linearity on its own suffices to prevent use-after-free errors when values are not aliased (a freed value is out of scope for the rest of the expression), we still need another simple, yet powerful concept to provide us with the extra expressivity of aliasing without losing any of the benefits of linearity.

Fractional permissions provide exactly this. Concretely, types of (pointers to) arrays and matrices are parameterised by a fraction. A fraction is either 1 (2⁰) or exactly half of another fraction $(2^{-k}$, for natural k). The former represents complete ownership of that value: the programmer may mutate or free that value as they choose; the latter represents read-only access or a borrow: the programmer may read from the value but not write to or free it. Creating an

array/matrix gives you ownership of it, so too does having one (with a fractional permission of 2^0) passed in as an argument.

In NumLin, we can produce two aliases of a single array/matrix, by sharing it. If the original alias had a fractional permission of 2^{-k} then the two new aliases of it will have a fractional permission of $2^{-(k+1)}$ each. Thanks to linearity, the original array/matrix with a fractional permission of 2^{-k} will be out of scope after the sharing. When an array/matrix is shared as such, we can prevent the programmer from freeing or mutating it by making the types of free and set (for mutation) require a whole (2^0) permission.

If we have two aliases to the same matrix with identical fractional permissions $(2^{-(k+1)})$, we can recombine or unshare them back into a single one, with a larger 2^{-k} permission. As before, thanks to linearity, the original two aliases will be out of scope after unsharing.

Runtime Errors Aside from out-of-bounds indexing, matrix unsharing is one of only two operations that can fail at runtime (the other being dimension checks, such as for gemm). The check being performed is a simple sanity check that the two aliasing pointers passed to unshare point to the same array/matrix. Section 5 contains an overview of how we could remove the need for this by tracking pointer identities statically by augmenting the type system further.

Recursion The final feature of Numlin which makes it sufficiently expressive is recursion (and of course, conditional branches to ensure termination). Conditional branches are implemented by ensuring that both branches use the same set of linear values. A function can be recursive if it captures no linear values from its environment. Like with Many, this is enforced via simple syntactic restrictions on the definition of recursive functions.

2.2 Examples

Factorial Although a factorial function (Figure 1) may seem like an aggresively pedestrian first example, in a linearly typed language such as NumLin it represents the culmination of many features.

To simplify the design and implementation of NumLin's type system, recursive functions must have full type annotations (non-recursive functions need only their argument types annotated). Its body is a closed expression (with respect to the function's arguments), so it type-checks (since it does not capture any linear values from its environment).

The only argument is !x : !int. The ! annotation on x is a syntactic convenience for declaring the value to used intuitionistically, its full and precise meaning is described in Section 4.1.

The condition for an if may or may not use linear values (here, with $\mathbf{x} < 0$) | | $\mathbf{x} = 0$, it does not). Any linear values used by the condition would not be in scope in either branch of the if-expression. Both branches use \mathbf{x} differently: one ignores it completely and the other uses it twice.

4

Fig. 1. Factorial function in NumLin.

Fig. 2. Summing over an array in NumLin.

All numeric and boolean literals are implicitly wrapped in a Many and all primitives involving them return a !int, !bool or !elt (types of elements of arrays/matrices, typically 64-bit floating-point numbers). The short-circuting | | behaves in exactly the same way as a boolean-valued if-expression.

Summing over an Array Now we can add fractional permissions to the mix: Figure 2 shows a simple, tail-recursive implementation of summing all the elements in an array. There are many new features; first among them is !x0 : !elt, the type of array/matrix elements (64-bit floating point).

Second is ('x) (row: 'x arr) which is an array with a universally-quantified fractional permission. In particular, this means the body of the function cannot mutate or free the input array, only read from it. If the programmer did try to mutate or free row, then they would get a helpful error message (Figure 3).

Alongside taking a row: 'x arr, the function also returns an array with exactly the same fractional permission as the row (which can only be row). This is necessary because of linearity: for the caller, the original array passed in as an argument would be out of scope for the rest of the expression, so it needs to be returned and then rebound to be used for the rest of the function.

An example of this consuming and re-binding is in let (row, !x1) = row[i]. Indexing is implemented as a primitive get: 'x. 'x arr --o !int --o 'x arr * !elt. Although fractional permissions can be passed around explicitly (as done in the recursive call), they can also be automatically inferred at call sites: row[i] == get _ row i takes advantage of this convenience.

Fig. 3. Attempting to write to or free a read only array in NumLin.

```
let rec simp_oned_conv
        (!i : !int) (!n : !int) (!x0 : !elt)
        (write : z arr) ('x) (weights : 'x arr)
        : 'x arr * z arr =
    if n = i then (weights, write) else
    let !w0 <- weights[0]</pre>
                             in
    let !w1 <- weights[1]</pre>
                              in
    let !w2 <- weights[2]</pre>
    let !x1 <- write[i]</pre>
                              in
    let !x2 <- write[i + 1] in
    let written = write[i] := w0 *. x0 +. (w1 *. x1 +. w2 *. x2) in
    simp_oned_conv (i + 1) n x1 written _ weights in
  simp_oned_conv
;;
```

Fig. 4. Simplified one-dimensional convolution.

One-dimensional Convolution Figure 4 extends the set of features demonstrated by the previous examples by mutating one of the input arrays. A one-dimensional convolution involves two arrays: a read-only kernel (array of weights) and an input vector. It modifies the input vector *in-place* by replacing each write[i] with a weighted (as per the values in the kernel) sum of it and its neighbours; intuitively, sliding a dot-product with the kernel across the vector.

What's implemented in Figure 4 is a *simplified* version of this idea, so as to not distract from the features of NumLin. The simplifications are:

- the kernel has a length 3, so only the value of write[i-1] (prior to modification in the previous iteration) needs to be carried forward using x0
- write is assumed to have length n+1
- i's initial value is assumed to be 1
- x0's initial value is assumed to be write[0]
- the first and last values of write are ignored.

Mutating an array is implemented similarly to indexing one: a primitive set: z arr --o !int --o !elt --o z arr. It consumes the original array and returns a new array with the updated value. let written = write[i] := <exp> is just syntactic sugar for let written = set write i <exp>.

```
let !square ('x) (x : 'x mat) =
   let (x, (!m, !n)) = sizeM _ x in
   let (x1, x2) = shareM _ x in
   let answer <- new (m, n) [| x1 * x2 |] in
   let x = unshareM _ x1 x2 in
   (x, answer) in
   square
;;</pre>
```

Fig. 5. Linear regression (OLS): $\hat{\beta} = (\mathbf{X}^T \mathbf{X})^{-1} \mathbf{X}^T \mathbf{y}$

Since write: z arr (where z stands for k=0, representing a fractional permission of $2^{-k}=2^{-0}=1$), we may mutate it, but since we only need to read from weights, its fractional permission index can be universally-quantified. In the recursive call, we see _ being used explicitly to tell the compiler to *infer* the correct fractional permission based on the given arguments.

Squaring a Matrix The most pertinent aspect of NumLin is the types of its primitives. While the types of operations such as get and set might be borderline obvious, the types of BLAS/LAPACK routines become an incredibly useful, automated check for using the API correctly.

Figure 5 shows how a linearly-typed matrix squaring function may be written in NumLin. It is a *non-recursive* function declaration (the return type is inferred). Since we would like to be able to use a function like **square** more than once, it is marked with a ! annotation (which also ensures it captures no linear values from the surrounding environment).

To square a matrix, first, we extract the dimensions of the argument x. Then, because we need to use x twice (so that we can multiply it by itself) but linearity only allows one use, we use shareM: 'x. 'x mat --o 'x s mat * 'x s mat to split the permission 'x (which represents 2^{-x}) into two halves ('x s, which represents $2^{-(x+1)}$).

Even if x had type z mat, sharing it now enforces the assumption of all BLAS/LAPACK routines that any matrix which is written to (which, in NUM-LIN, is always of type z mat) does not alias any other matrix in scope. So if we did try to use one of the aliases in mutating way, the expression would not type check, and we would get an error similar to the one in Figure 3.

The line let <code>answer <- new (m,n) [| x1 * x2 |]</code> is syntactic sugar for first creating a new $m \times n$ matrix (let <code>answer = matrix m n)</code> and then storing the result of the multiplication in it (let ((x1, x2), answer) = gemm 1. _ (x1, false) _ (x2, false) 0. answer). false means the matrix should not be accessed with indices transposed.

By using some simple pattern-matching and syntactic sugar, we can:

- write normal-looking, apparently non-linear code
- use matrix expressions directly and have a call to an efficient call to a BLAS/LAPACK routine inserted with appropriate re-bindings

Fig. 6. Linear regression (OLS): $\hat{\beta} = (\mathbf{X}^T \mathbf{X})^{-1} \mathbf{X}^T \mathbf{y}$

 retain the safety of linear types with fractional permissions by having the compiler statically enforce the aliasing and read/write rules implicitly assumed by BLAS/LAPACK routines.

Linear Regression In Figure 6, we wish to compute $\hat{\beta} = (\mathbf{X}^T \mathbf{X})^{-1} \mathbf{X}^T \mathbf{y}$. To do that, first, we extract the dimensions of matrix \mathbf{x} . Then, we say we would like $\mathbf{x}\mathbf{y}$ to be a new matrix, of dimension $m \times 1$, which contains the result of $\mathbf{X}^T \mathbf{y}$ (using syntactic sugar for matrix and gemm calls similar to that used in Figure 5, with a $\hat{\mathbf{T}}$ annotation on \mathbf{x} to set \mathbf{x} 's 'transpose indices'-flag to true).

However, the line let $x_T_x < -$ new (m,m) [| $x^T * x$ |], works for a slightly different reason: that pattern is matched to a BLAS call to $(syrk true 1. x 0. x_T_x)$, which only uses x once. Hence x can appear *twice* in the *pattern* without any calls to share.

After computing x_T_x, we need to invert it and then multiply it by xy. The BLAS routine posv: z mat --o z mat --o z mat * z mat does exactly that: assuming the first argument is symmetric, posv mutates its second argument to contain the desired value. Its first argument is also mutated to contain the (upper triangular) Cholesky decomposition factor of the original matrix. Since we do not need that matrix (or its memory) again, we free it. If we forgot to, we would get a Variable to_del not used error. Lastly, we return the answer alongside the untouched input matrices (x,y).

L1-Norm Minimisation on Manifolds L1-Norm minimisation is often used in optimisation problems, as a *regularisation* term for reducing the influence of outliers. Although the below formulation [2] is intended to be used with *sparse* computations, Numlin's current implementation only implements dense ones. However, it still serves as a useful example of explaining Numlin's features.

Figure 7 shows even more pattern-matching. Patterns of the form let <id><- [| beta * c + alpha * a * b |] are also desugared to gemm calls. Primitives like transpose: 'x. 'x mat --o 'x mat * z mat and eye: !int --o z mat allocate new matrices; transpose returns the transpose of a given matrix and eye k evaluates to a $k \times k$ identity matrix.

```
let !11_norm_min (q : z mat) (u : z mat) =
  let (u, (!_n, !k)) = sizeM _ u in
  let (u, u_T) = transpose _ u in
  let (tmp_n_n , q_inv_u ) = gesv q u in
  let i = eye k in
  let to_inv <- [| i + u_T * q_inv_u |] in
  let (tmp_k_k, inv_u_T ) = gesv to_inv u_T in
  let () = freeM tmp_k_k in
  let answer <- [| 0. * tmp_n_n + q_inv_u * inv_u_T |] in
  let () = freeM q_inv_u in
  let () = freeM inv_u_T in
  answer in

11_norm_min
;;</pre>
```

Fig. 7. L1-norm minimisation on manifolds: $\mathbf{Q}^{-1}\mathbf{U}(\mathbf{I} + \mathbf{U}^{T}\mathbf{Q}^{-1}\mathbf{U})^{-1}\mathbf{U}^{T}$

We also see our first example of re-using memory for different matrices: like with to_del and posv in the previous example, we do not need the value stored in tmp_5_5 after the call to gesv (a primitive similar to posv but for a non-symmetric first argument). However, we can re-use its memory much later to store answer with let answer <- [| 0. * tmp_5_5 + q_inv_u * inv_u_T |]. Again, thanks to linearity, the identifiers q and tmp_5_5 are out of scope by the time answer is bound. Although during execution, all three refer to the same piece of memory, logically they represent different values throughout the computation.

Kalman Filter A Kalman Filter [3] is a an algorithm for combining prior knowledge of a state, a statistical model and measurements from (noisy) sensors to produce an estimate a more reliable estimated of the current state. It has various applications (navigation, signal-processing, econometrics) and is relevant here because it is usually presented as a series of complex matrix equations.

Figure 8 shows a NumLin implementation of a Kalman filter (equations in Figure 9). A few new features and techniques are used in this implementation:

- sym annotations in matrix expressions: when this is used, a call to symm (the equivalent of gemm but for symmetric matrices so that only half the operations are performed) is inserted
- copyM_to is used to re-use memory by overwriting the contents of its second argument to that of its first (erroring if dimensions do not match)
- let $new_r \leftarrow new [| r_2 |]$ creates a copy of r_2
- potrs _chol_r data_2 uses a pre-computed Cholesky decomposition to multiply data $2 = H\mu \text{data by r } 2 = (R + H\Sigma H^T)^{-1}$
- a lot of memory re-use; the following sets of identifiers alias each other:
 - r_1 and r_2
 - data_1, data_2 and sol_data

```
let !kalman
        ('s) (sigma : 's mat) (*n,n*)
        ('h) (h : 'h mat)
                                (* k.n *)
        ('m) (mu : 'm mat)
                                (*n,1*)
                                (* k, k *)
        (r_1 : z mat)
        (data_1 : z mat)
                                (* k, 1 *) =
        let (h, (!k, !n)) = sizeM _ h in
        let sigma_h \leftarrow new(k, n)[|h * sym(sigma)|] in
        let r_2 \leftarrow [| sigma_h * h^T + r_1 |] in
(*17*)
(*18*) let data_2 <- [| h * mu - data_1 |] in
(*19*) let (h, new_h) = copyM_to _ h sigma_h in
(*20*) let new_r <- new [| r_2 |] in
(*21*) let (chol_r, sol_h) = posv new_r new_h in
(*23*) let (chol_r, sol_data) = potrs _ chol_r data_2 in
        let () = freeM (* k, k *) chol_r in
(*24*) let h_sol_h <- new (n, n) [| h^T * sol_h |] in
        let () = freeM (* k, n *) sol_h in
(*25*) let h_sol_data <- new (n, 1) [| h^T * sol_data |] in
(*26*) let mu_copy <- new [| mu |] in
        let new_mu <- [| sym (sigma) * h_sol_data + mu_copy |] in</pre>
(*27*)
        let () = freeM (* n, 1 *) h_sol_data in
(*28*)
        let h_sol_h_sigma <- new (n,n) [| h_sol_h * sym(sigma) |] in</pre>
(*29*) let (sigma, sigma_copy) = copyM_to _ sigma h_sol_h in
(*30*) \quad \texttt{let new\_sigma} \mathrel{<-} [| \ \texttt{sigma\_copy} \ - \ \texttt{sym} \ (\texttt{sigma}) \ * \ \texttt{h\_sol\_h\_sigma} \ |] \ \texttt{in}
        let () = freeM (* n, n *) h_sol_h_sigma in
        ((sigma, (h, (mu, (r_2, sol_data)))), (new_mu, new_sigma)) in
      kalman
      ;;
```

Fig. 8. Kalman filter: see Figure 9 for the equations this code implements. Line numbers in comments refer to equivalent lines in a C implementation (Figure 18).

```
new_h and sol_h
h_sol_h, sigma_copy and new_sigma
mu_copy and new_mu.
```

The NumLin implementation is much longer than the mathematical equations for two reasons. First, the NumLin implementation is a let-normalised form of the Kalman equations: since there a large number of unary/binary (and occasionally ternary) sub-expressions in the equations, naming each one line at a time makes the implementation much longer. Second, NumLin has the additional task of handling explicit allocations, aliasing and frees of matrices. However, it is exactly this which makes it possible (and often, easy) to spot additional opportunities for memory re-use. Furthermore, a programmer can explore those opportunities easily because NumLin's type system statically enforces correct memory management and the aliasing assumptions of BLAS/LAPACK routines.

$$\mu' = \mu + \Sigma H^T (R + H \Sigma H^T)^{-1} (H \mu - \text{data})$$

$$\Sigma' = \Sigma (I - H^T (R + H \Sigma H^T)^{-1} H \Sigma)$$

State the fundamental lemma, and sketch the proof a little

4 Implementation

Talk about how you implemented NumLin and the general architecture. Talk about how simple everything is, and also about how implementing inference for fractions is.

4.1 Implementation Strategy

NumLin transpiles to OCaml and its implementation follows the structure of a typical domain-specific language (DSL) compiler. Although NumLin's current implementation is not as an embedded DSL, its the general design is simple enough to adapt to being so and also to target other languages.

Alongside the transpiler, a 'Read-Check-Translate' loop, benchmarking program and a test suite are included in the artifacts accompanying this paper.

- 1. Parsing. A generated, LR(1) parser parses a text file into a syntax tree. In general, this part will vary for different languages and can also be dealt with using combinators or syntax-extensions (the EDSL approach) if the host language offers such support.
- 2. **Desugaring**. The syntax tree is then desugared into a smaller, more concise, abstract syntax tree. This allows for the type checker to be simpler to specify and easier to implement.
- 3. Matrix Expressions are also desugared into the abstract syntax tree through some simple pattern-matching.
- 4. **Type checking**. The abstract syntax tree is explicitly typed, with some inference to make writing typical programs more convenient.

5. Code Generation. The abstract syntax tree is translated into OCaml, with a few 'optimisations' to produce more readable code. This process is type-preserving: NumLin's type system is embedded into OCaml's (Figure 11), and so the OCaml type checker acts as a sanity check on the generated code.

A very pleasant way to use NumLin is to have the build system generate code at *compile-time* and then have the generated code be used by other modules like normal OCaml functions. This makes it possible and even easy to use NumLin alongside existing OCaml libraries; in fact, this is exactly how the benchmarking program and test-suite use code written in NumLin.

Desugaring, Matrix Expressions and Type Checking Desugaring is conventional, outlined in Figure 16. Matrix expression are translated into BLAS/LAPACK calls via purely syntactic pattern-matching, outlined in Figure 10. Type checking is mostly standard for a linearly typed language, with the exception of fractional permission inference. Because all functions must have their argument types explicitly annotated, inferring the correct fraction at a call-site is simply a matter of unification.

WHAT MORE CAN/SHOULD WE SAY HERE?

Code Generation is a straightforward mapping from NumLin's core constructs to high-level OCaml ones. We embed NumLin's type- and term-constructors into OCaml as a sanity check on the output (Figure 11).

This is also useful when using Numlin from within OCaml; for example, we can use existing tools to inspect the type of the function we are using (Figure 12). It is worth reiterating that only the type- and term- constructors are translated into OCaml, Numlin's precise control over linearity and aliasing are not brought over.

We actually use this fact to our advantage to clean up the output OCaml by removing what would otherwise be redundant re-bindings (Figure 13). Combined with a code-formatter, the resulting code is not obviously correct and exactly what an expert would intend to write by hand, but now with the guarantees and safety of Numlin behind it. A small example is shown in Figure 14, a larger one in Figure 17.

4.2 Performance Metrics

Here, evaluate the performance of the examples from the second section. Compare with your C implementations, and perhaps as well as the straightforward math transcribed into (Matlab/R/Numpy?).

5 Discussion and Related Work

The main point we want to make is that using linear types for BLAS is an "obvious" idea, but is surprisingly under-explored.

```
let v \leftarrow x[e] in e \Rightarrow let (x,!v) = x[e] in e
                                                                                            (similarly for matrices)
let x_2 \leftarrow \text{new} [|x_1|] \text{ in } e \Rightarrow \text{let } (x_1, x_2) = \text{copyM} \_ x_1 \text{ in } e
        let x_2 \leftarrow [\mid x_1 \mid] in e \Rightarrow let (x_1, x_2) = \mathbf{copyM} to x_1 x_2 in e
                                          M ::= X \mid X^T \mid \operatorname{sym}(X)
      let Y \leftarrow \mathbf{new} \ (n,k) \ [| \ \alpha M_1 M_2 \ |] \ \mathbf{in} \ e \Rightarrow
            let Y = \text{matrix } n \text{ } k \text{ in let } Y \leftarrow [\mid \alpha M_1 M_2 + 0Y \mid] \text{ in } e
      let Y \leftarrow [|\alpha XX^T + \beta Y|] in e \Rightarrow
            let (X,Y) = syrk false \alpha X \beta Y in e
      let Y \leftarrow [|\alpha X^T X + \beta Y|] in e \Rightarrow
            let (X,Y) = syrk true \alpha \ \_ \ X \ \beta \ Y in e
      let Y \leftarrow [|\alpha \operatorname{sym}(X_1) X_2 + \beta Y|] in e \Rightarrow
            let ((X_1, X_2), Y) = symm false \alpha X_1 X_2 \beta Y in e
      let Y \leftarrow [|\alpha X_2 \operatorname{sym}(X_1) + \beta Y|] in e \Rightarrow
            let ((X_1, X_2), Y) = symm true \alpha X_1 X_2 \beta Y in e
      let Y \leftarrow [|\alpha X_1^{T?} X_2^{T?} + \beta Y|] in e \Rightarrow
            let ((X_1, X_2), Y) = \text{gemm } \alpha = (X_1, \frac{\text{true}}{\text{false}}) = (X_2, \frac{\text{true}}{\text{false}}) \beta Y \text{ in } e
```

                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                   /*32*/
                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                            /*ZZ*/
                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                           /*30*/
```

and OCaml FFI support for C is better and easier to use than that for Fortran. A distinct 'measure_kalman' function that sandwiches Fig. 18. CBLAS/LAPACKE implementation of a Kalman filter. I used C instead of Fortran because it is what Owl uses under the hood a call to this function with getrusage is omitted for brevity.
